RANDOM EXCHANGES OF INFORMATION

DAVID W. BOYD* AND
J. MICHAEL STEELE,** The University of British Columbia

Abstract

Suppose that \( n \) persons each know a different piece of information, and that whenever a pair of persons talk on the telephone each tells the other all the information that he knows at the time. If calls are made at random, we show that the expected number of calls necessary until everyone knows all \( n \) pieces of information is asymptotically \( 1.5 \, n \log n \). This sharpens an earlier result of J. W. Moon.

CONTAGION; RANDOM MATRIX; TELEPHONE PROBLEM

1. Introduction

The object of this paper is to give a solution to a problem raised by Moon [4] concerning a model of random contagion. Of the several ways to describe this model one has become traditional. Suppose that \( n \) persons each know a different piece of information, and whenever two of them talk on the telephone each tells the other all the information he knows at the time. The way in which information spreads through such a system suggests a variety of problems.

The popular 'telephone problem', attributed to A. V. Boyd in [4] and [5], is to determine the minimum number of calls \( c(n) \) required until everyone has learned all \( n \) pieces of information. It is clear that \( c(1) = 0 \), \( c(2) = 1 \) and \( c(3) = 3 \), and A. V. Boyd exhibited a scheme of calls to show that if \( n \geq 4 \), \( c(n) \leq 2n - 4 \) (such a scheme is described in [5]). He conjectured that \( c(n) = 2n - 4 \) for \( n \geq 4 \), and this was proved independently by Tijdeman [5], Bumby and Spencer [1], and Hajnal, Milner and Szemerédi [3].

Moon [4] considered instead the situation in which the calls are made at random (i.e. the operator chooses two different persons at random from the \( n \) and places the call). Suppose \( C \) calls are made before each person knows all the

657
information. The problem is to determine \( E(C) \), the expected value of \( C \). Moon
gave an elegant proof of the bounds

\[
(1 - \varepsilon)n \log n \leq E(C) \leq (2 + \varepsilon)n(\log n)^2,
\]

where \( \varepsilon > 0 \) and \( n \) is sufficiently large. Here we will prove the following more
precise result.

**Theorem.**

\[
E(C) = \frac{3}{2} n \log n + O(n(\log n)^{3/2}).
\]

A different formulation of the telephone problem, attributed to Wirsing in [5],
may serve to put our result in a more general context. Let \( B_i \) be the \( n \times n \) matrix
with all entries 0 except for a 1 in the \((i, j)\) and \((j, i)\) positions. Let \( A(0) = I \) and
\( A(t) = A(t - 1)(I + B_i) \) if there is a call between persons \( i \) and \( j \) at time \( t \). Then
\( a_{jm}(t) > 0 \) if and only if the \( m \)th person knows the \( k \)th piece of information at
time \( t \). One sees this by induction, after observing that \( A(t) \) is obtained from
\( A(t - 1) \) by replacing the \( i \)th and \( j \)th columns by their sum, leaving all other
columns unchanged. Thus, if \( m = i \) or \( j \), then \( a_{jm}(t) > 0 \) if and only if at least one
of \( a_{ii}(t - 1) > 0 \) or \( a_{jj}(t - 1) > 0 \) holds, while if \( m \neq i, j \) then \( a_{jm}(t) = a_{jm}(t - 1) \).
This corresponds to the fact that \( i \) and \( j \) know the \( k \)th piece of information at
time \( t \) if and only if one of them knew it at time \( t - 1 \). Thus, if the \( B_i \) are chosen
at random, \( C \) is the first time at which \( A(t) \) is a strictly positive matrix.

**2. The lower bound**

Let \( T_i \) be the first time at which everyone knows person \( i \)'s original
information, and let \( T^*_i \) be the first time at which person \( i \) knows everyone's
information. In terms of the matrix formulation, \( T_i \) is the first time that the \( i \)th
row of \( A(t) \) has no zeros, and \( T^*_i \) is the first time that the \( i \)th column of \( A(t) \) has
no zeros. Since each \( B_i \) is symmetric, it is clear that one has the following result.

**Lemma.** The distributions of the vectors \((T_1, \cdots, T_n)\) and \((T^*_1, \cdots, T^*_n)\) are
equal.

By definition, \( C = \max_{1 \leq i \leq n} T_i = \max_{1 \leq i \leq n} T^*_i \). Moon used the observation that
\( E(C) \geq E(T_i) \) to obtain his lower bound. To improve this bound, it seems
necessary to consider all the \( T_i \). Let \( T^*_{(i)} \) be the \( i \)th largest of the \( T^*_i \) so that
\( T^*_{(1)} \leq \cdots \leq T^*_{(n)} = C \). Now let \( R_i \) be the number of calls until each of the
persons \( 1, 2, \cdots, i \) has received a call. Then, for \( i \leq n - 2 \)

\[
E(C) \geq E(T^*_{(i)}) + E(R_{n-i-1}).
\]

This follows from the fact that, at time \( T^*_{(i)} \) either \( i \) or \( i + 1 \) persons know
everything (since a call involves two callers). For the remaining \( n - i - 1 \) persons to learn everything, each must receive at least one call. If one defines \( E(R_i) = E(R_{i-1}) = 0 \), then (1) is obviously valid for \( i = n - 1 \) and \( i = n \). Averaging (1) over \( i \), we have

\[
E(C) \geq n^{-1} \sum_{i=1}^{n} E(T_{i}^{*}) + n^{-1} \sum_{i=1}^{n} E(R_i).
\]

But, from the lemma,

\[
\sum_{i=1}^{n} E(T_{i}^{*}) = \sum_{i=1}^{n} E(T_{i}) = \sum_{i=1}^{n} E(T_i) = nE(T_i).
\]

Combining (2) and (3) gives

\[
E(C) \geq E(T_i) + n^{-1} \sum_{i=1}^{n} E(R_i).
\]

As in [4], \( E(T_i) \) can be calculated by observing that \( T_i = X_1 + \cdots + X_{n-i} \), where \( X_i \) is the number of calls after \( i \) persons know person 1's information until \( i + 1 \) know it. The \( X_i \) are independent and geometrically distributed with parameter \( p_i = (2i(n - i))/(n(n - 1)) \). Hence \( E(X_i) = 1/p_i \) and

\[
E(T_i) = \sum_{i=1}^{n} p_i^{-1} = \frac{n - 1}{2} \sum_{i=1}^{n} \left( \frac{1}{i} + \frac{1}{n-i} \right) = n \log n + O(n).
\]

The calculation of \( E(R_i) \) is slightly more complicated. We observe that the process of generating calls at random is equivalent to the following: first generate numbers \( N_1, N_2, \ldots \) at random from \( \{1, 2, \ldots, n\} \). Form the sequence of pairs \((N_1, N_2), (N_3, N_4), \ldots \). Delete from this sequence any pair for which \( N_{2k+1} = N_{2k} \), obtaining a sequence \((N_1, N_2), \ldots \). Then a call is made at time \( t \) between \( N_{2k-1} \) and \( N_{2k} \). Thus \( R_i \) is the time at which \( N_{i+1}, \ldots, N_{2m} \) first contains all of \( \{1, \ldots, i\} \). Let \( S \) be the first time at which \( N_1, \ldots, N_k \) contains all of \( \{1, \ldots, i\} \) and \( M \) be the first time at which \( N_{n-1}, \ldots, N_{2m} \) contains \( \{1, \ldots, i\} \). Clearly \( M \cong S/2 \). Next let \( A_k \) be 1 if \( N_{2k+1} = N_{2k} \) and 0 otherwise. Put \( K = \sum_{k=1}^{n} A_k \) and note that \( R_i \cong M - K \). Since \( E(A_k) = 1/n \), Wald's lemma ([2], p. 380), shows \( E(K) = E(M)/n \), so

\[
E(R_i) \cong (1 - n^{-1})E(M) \cong (1 - n^{-1})E(S)/2.
\]

But \( S = B_1 + \cdots + B_i \), where \( B_i \) is the time between the occurrence of the \( (j-1) \)th and \( j \)th elements of \( \{1, 2, \ldots, i\} \) in \( N_1, \ldots, N_k \). So \( B_i \) is distributed geometrically with parameter \( (i-j+1)/n \). Hence \( E(B_i) = n/(i-j+1) \). So

\[
E(S) = n \sum_{i=1}^{n} j^{-1} \cdot n \sum_{i=1}^{n} E(R_i) \cong \frac{1}{2} n \log n + O(n),
\]

\[
E(C) \geq E(S) + n^{-1} \sum_{i=1}^{n} E(R_i).
\]
and thus we have, combining (4), (5) and (7),

\[ E(C) \geq \frac{3}{2} n \log n + O(n). \]

3. The upper bound

We first note that

\[ P(C \leq u) = P\left( \left( \max_{i=1}^{n} T_i \right) \leq u \right) \leq nP(T_1 \leq u). \]

Now, using the well-known formula \( E(C) = \int_0^\infty P(C \geq u)du \) ([2], p. 148), we see that, for any \( t > 0 \),

\[ E(C) = \int_0^t P(C \geq u)du + \int_t^\infty P(C \geq u)du \]

\[ \leq t + n \int_t^\infty P(T_1 \geq u)du. \]

The exact distribution of \( T_1 \) is known from Section 2, and thus

\[ P(T_1 \geq u) \leq e^{-u}E(e^{x_1}) = e^{-u} \frac{\pi e^{x_1}}{(1-qe^{x_1})}, \]

where \( p_i = (2i(n-i))/(n(n-1)) \), and \( q = 1 - p_i \). In (10) we must have \( 1 - q_i e^{x_1} > 0 \) so \( e^{-x_1} > 1 - 2/n \). Write \( \pi_n = \Pi_{i=1}^{n-1} p_i e^{x_1}/(1-qe^{x_1}) \) and then substitute (10) into (9) to obtain

\[ E(C) \leq t + ns^{-1}e^{-u} \pi_n. \]

Setting \( e^{-x_1} = 1 - c/n \) with \( c < 2 \), we have

\[ \log \pi_n = -\sum_{i=1}^{n-1} \log(1 - c/(np_i)) = \sum_{i=1}^{n-1} \sum_{j=1}^{i} j^{-1}(c/(np_j))^j. \]

If we set \( b_i = \sum_{j=1}^{i} (c/(np_j))^j \), we have (as in [5]), \( b_i \leq c \log n \), and

\[ \sum_{i=2}^{n-1} j^{-1}b_j < \sum_{i=2}^{n-1} (c/2)^j \left( \frac{n - 1}{i(n - i)} \right)^j < \sum_{i=1}^{n-1} \left( \frac{c}{2i(n - i)} \right)^2 \left( 1 - c/2i \right)^{-1}, \]

since \( (n - 1)/(i(n - i)) \leq 1 \) for \( 1 \leq i \leq n - 1 \). Now

\[ \sum_{i=2}^{n-1} \left( \frac{n - 1}{i(n - i)} \right)^2 = \sum_{i=1}^{n-1} \left[ \frac{1}{i^2} + \frac{1}{n(n - i)} \right] = \frac{1}{n(n - i)} \]

so that, by (12), there is a constant \( M \) for which

\[ \log \pi_n \leq c \log n + M(1 - c/2)^{-1}. \]
Since $s > 1 - e^{-s} = c/n$, (11) now becomes

$$E(C) \leq t + c^{-1} \exp \{ 2 \log n - n^{-1} ct + c \log n + M(1 - c/2)^{-1} \}. $$

On setting $c = 2(1 - (\log n)^{-1/2})$ and $t = \frac{1}{2} n \log n + A n (\log n)^{1/2}$, the exponent in (13) becomes

$$\log n - (2A - 1 - M) (\log n)^{1/2} + 2A = \log n + 2A,$$

if we choose $A = (M + 1)/2$. Then (13) becomes

$$E(C) \leq \frac{3}{2} n \log n + A n (\log n)^{1/2} + c^{-1} n \exp (2A)$$

$$= \frac{3}{2} n \log n + O(n (\log n)^{1/2}),$$

which completes the proof of the theorem.
